AN EMPIRICAL UBVRIJHK COLOR-TEMPERATURE CALIBRATION FOR STARS

GUY WORTHEY AND HYUN-CHUL LEE

Department of Physics and Astronomy, Washington State University, Pullman, WA 99164-2814

Draft version May 1, 2006

ABSTRACT

A collection of Johnson/Cousins photometry for stars with known $[\text{Fe}/\text{H}]$ is used to generate color-color relations that include the abundance dependence. Literature temperature and bolometric correction dependences are attached to the color relations. The JHK colors are transformed to the Bessell & Brett (1988) homogenized system. The main result of this work is the tabulation of seven colors and the V -band bolometric correction as a function of T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ for $-1.06 < V - K < 10.2$ and an accompanying interpolation program. Improvements to the present calibration would involve filling photometry gaps, obtaining more accurate and on-system photometry, knowing better $\log g$ and $[\text{Fe}/\text{H}]$ values, improving the statistics for data-impovertished groups of stars such as K dwarfs, applying small tweaks in the processing pipeline, and obtaining better empirical temperature and bolometric correction relations, especially for supergiants and M stars. A way to estimate dust extinction from M dwarf colors is pointed out.

Subject headings: stars: fundamental parameters — stars: general

1. INTRODUCTION

Stellar evolutionary tracks and isochrones calculate physical radius, luminosity, and effective temperature. In order to compare with observable quantities, almost always magnitudes and colors, a transformation is essential. The need for such transformations is also felt when integrated light models (population synthesis models) are constructed for comparisons to colors from galaxies and star clusters. Color-temperature transformations are also used in spectral abundance analysis, design of observing strategies, computation of selection effects, and a host of incidental astronomical problems.

One way to approach this problem is to calculate line-blanketed synthetic spectra and integrate under filter transmission functions to get fluxes, which are then zeroed by comparison with Vega or other convenient standard (Buser & Kurucz 1992; Bell & Gustafsson 1989). This is a convenient approach, but vulnerable to errors in all of the steps of the process: incorrect atmosphere structures, incorrect or incomplete line lists, incorrect treatment of convection, turbulence, non-LTE effects, or line broadening, incorrect filter transmissions, inaccurate spectrophotometry of the comparison star or stars, and finally, the photometry of the comparison star itself. Examples of suspicious circumstances include the fact that the blue edge of the U filter is set by the earth's atmosphere and will inevitably change with time and place, the fact that half the lines in the solar spectrum have yet to be identified (Kurucz 1992a), and the fact that the absolute flux calibration for stars is uncertain by about 5% [e.g. Berriman et al. (1992)] Recent examples of synthetic calibrations are VandenBerg & Clem (2003), Vazdekis et al. (1996), Lejeune et al. (1998), and Houdashelt et al. (2000).

Despite the need for empirical alternatives, the present paper appears to be the first attempt at empirically calibrating many colors for all stellar temperatures as a function of abundance and gravity. The inspiration for this work comes from Green (1988). Green describes a global color- T_{eff} calibration generated for attachment to the

Revised Yale Isochrones (Green et al. 1987) that provides colors tabulated for a (long) list of temperatures, surface gravities, and $[\text{Fe}/\text{H}]$ values. The strategy used by Green was to begin with empirical color-color relations for solar-metallicity stars, and adopt the ridge line as the starting place. Then one attaches a color- T_{eff} relation and adds $[\text{Fe}/\text{H}]$ and gravity dependence by working differentially within synthetic color tables. The approach here is to do the same, except that the gravity and abundance dependences are fit to the stars themselves. Synthetic colors are used at very low weight to guide the fits where there are few or no stars in the sample (e.g. metal-poor M giants). Only oxygen-rich stars are considered here. Color-temperature relations for carbon-rich giants are given in Bergeat et al. (2001).

This paper is divided into sections on procedure, literature comparisons, and a concluding section. Supporting material (color-temperature table and interpolation program) is available at <http://astro.wsu.edu/models/>.

2. PROCEDURE

2.1. Stellar Data

The nucleus of the photometry catalog is the compilation of Morel & Magnenat (1978), which is firmly Johnson-system. Several other photometry sources were included. These include Veeder (1974), Bessell (1991), Stetson (1981), da Costa & Armandroff (1990), Wood, Bessell, & Fox (1983), Wood & Bessell (1983), von Braun et al. (1998), Carney (1983), Cohen et al. (1978), Elias et al. (1982), Elias et al. (1985), Frogel et al. (1978), Frogel et al. (1979), Persson et al. (1980), Cohen et al. (1980), Frogel et al. (1981), da Costa et al. (1981), Cohen & Frogel (1982), Frogel et al. (1983), Frogel et al. (1990), Leggett et al. (2001), Dahn et al. (2002), and the 2MASS point source catalog.

As a first try at assigning abundance measurements to the list of 4163 stars, the Cayrel de Strobel et al. (2001), McWilliam (1990), and Edvardsson et al. (1993) abundance catalogs were consulted. M giants with good pho-

tometry were artificially assigned an $[\text{Fe}/\text{H}]$ of zero except those that belong to clusters, in which case the cluster metallicity was adopted. M dwarfs were assigned an $[\text{Fe}/\text{H}]$ based on their kinematics, most of which came from Veeder (1974). Young disk objects were assigned $[\text{Fe}/\text{H}] = -0.1$, old disk -0.5 , and halo -1.5 . Cluster stars naturally inherited the cluster metallicity. Cluster abundances came from mostly secondhand compilations (Worthey et al. 1994; von Braun et al. 1998; Frogel et al. 1978). An abundance of $+0.3$ was adopted for NGC 6791 (Worthey & Jowett 2003). LMC field stars were assigned -0.3 and stars in the SMC -0.6 . Some supergiants and very hot stars were artificially assigned $[\text{Fe}/\text{H}] = 0$ when no abundance was available, but many had literature abundances. Unfortunately, a complete citing of the abundance sources cannot be given, as notes on some of the (perhaps 5%) abundance assignments have been lost. A total of 1954 useable stars had abundances, although the number is considerably less for any given photometric color. Odd holes appear in the final data set. For instance, the primary source for M dwarf colors is Veeder (1974) from which J -band data is missing. U -band data is hard to find for cool stars. Available R -band data has gaps as well.

Solar metallicity mean relations for all spectral types from Johnson (1966) and Bessell & Brett (1988) were included in the list, with $[\text{Fe}/\text{H}] = -0.1$ assumed for these “stars”.

2.2. Photometric Systems

Perhaps the reason no one has done this exercise before is because photometric systems are such a mess. The Morel & Magnenat (1978) catalog is on the “Johnson” photometric system. For colors involving RI , the target system was “Cousins” and we applied the transformation equations of Bessell (1979) and Bessell (1983) to transform the Johnson data except for $R-I$, for which we used a tracing of Figure 3 from Bessell (1983) rather than the formula given in the paper. Additional optical data that was already on the Cousins system was left there.

Infrared data was imported from 5 different systems (and this is mild compared to the number of systems that have proliferated over the years). As a target system, we chose the homogenized system of Bessell & Brett (1988). Transformations from Johnson-system, CIT-system, and AAO-system were used as provided in Bessell & Brett (1988). Some 2MASS data, mostly attached to NGC 6791 stars in the present stellar catalog, were transformed via Carpenter (2001) formulae to the Bessell & Brett (1988) system.

Corrections for interstellar extinction were done using the Cardelli et al. (1989) extinction curve. Note that corrections are applied differently for Johnson RI than for Cousins RI since the filters are at substantially different wavelengths. Such wavelength differences cause negligible correction differences at infrared wavelengths.

2.3. Color-color Fitting

The photometrically-homogenized, dereddened stellar data were then presented to a series of additional processing steps. A multivariate polynomial fitting program (a modification of the one used in Worthey et al. (1994) to fit spectral indices as a function of stellar atmosphere parameters) was applied to the data. The de-

FIG. 1.— The $U-B$, $V-K$ color-color diagram for uncultured stars. Stars have different symbol types for metal rich ($[\text{Fe}/\text{H}] > -0.2$), metal-poor ($[\text{Fe}/\text{H}] < -1.2$), and intermediate abundance ranges. Calibrations for typical giant and typical dwarf gravities are drawn in solid for $[\text{Fe}/\text{H}] = 0$, dashed for $[\text{Fe}/\text{H}] = -1$, and dotted for $[\text{Fe}/\text{H}] = -2$. Most carbon stars (asterisks) are not plotted as they stretch beyond the plot limits along a line from the plotted ones up to $(V-K, U-B) \approx (6, 6)$.

pendent variable chosen was $V-K$ because it is monotonically increasing with temperature and insensitive to abundance. $V-K$ is a fabulous temperature indicator in stars cooler than the sun, and, because of its monotonicity, can still serve as a temperature-like variable for hotter stars. Terms of up to order $(V-K)^6$ could be included, and up to quadratic terms of $\log g$, $[\text{Fe}/\text{H}]$, and cross-terms. Chemically peculiar stars such as carbon stars were excluded from the fit. The color range was divided into 5 overlapping sections and each range was independently fit. The specific polynomial terms allowed in the fit could be different for each section. This allowed, for instance, $[\text{Fe}/\text{H}]$ sensitivity to be manually phased out if desired. The fits were done many times. Outlier data points were rejected manually with the aid of a graphical interface that allowed the name and parameters of each star to be scrutinized before rejection.

The final polynomials were combined in tabular form, using a weighted-mean scheme wherein the middle of each $V-K$ section was weighted strongly compared to the edges of each section. $[\text{Fe}/\text{H}]$ and $\log g$ were tabulated in 0.5 dex intervals, $-2.5 \leq [\text{Fe}/\text{H}] \leq 0.5$, and $-0.5 \leq \log g \leq 5.5$. The resultant color-color relations are illustrated in Figures 1, 2, 3, 4, 5, and 6. All stars, even if they were rejected during the fitting process, are included in the figures. Carbon stars are included, but only for illustrative purposes; fits were not attempted.

For very hot stars of O and B spectral type an additional color-color table was crafted by hand from either summary color-spectral type relations or from our own color-color relations was employed to refine the color-color relations for the hottest stars. The sources consulted were Schmidt-Kaler (1982); Tokunaga (2000); Vacca et al. (1996), and our own color-color plots. There is basically no abundance leverage for very hot stars, so

FIG. 2.— The $B-V$, $V-K$ color-color diagram for uncalled stars. Stars have different symbol types for metal rich ($[\text{Fe}/\text{H}] > -0.2$), metal-poor ($[\text{Fe}/\text{H}] < -1.2$), and intermediate abundance ranges. Calibrations for typical giant and typical dwarf gravities are drawn in solid for $[\text{Fe}/\text{H}] = 0$, dashed for $[\text{Fe}/\text{H}] = -1$, and dotted for $[\text{Fe}/\text{H}] = -2$. Carbon stars are shown as asterisks.

FIG. 3.— The $V-R$, $V-K$ color-color diagram for uncalled stars. Symbols and line styles are as in Figure 2.

we assumed a zero metallicity dependence. These tabulated average values were included in the polynomial fits as if they were individual stars.

In the hot star regime, two uncertain areas came to light that deserve mention as regards dwarf vs. supergiant colors. First, in $U-B$, Schmidt-Kaler (1982) data imply a large and distinct color separation between dwarfs and supergiants, but the (few) supergiants available in our list did not follow the literature trend. Nor were the polynomials flexible enough to track these changes, mostly because, for O stars, the difference in surface gravity is very minor [4.15 (dwarfs) vs. 4.09 (supergiants) according to Vacca et al. (1996)]. In the end, we performed a weighted average between the polynomial

FIG. 4.— The $V-I$, $V-K$ color-color diagram for uncalled stars. Symbols and line styles are as in Figure 2.

FIG. 5.— The $J-K$, $V-K$ color-color diagram for uncalled stars. Symbols and line styles are as in Figure 2.

fits and the tabulated values. There is probably considerable uncertainty left in the supergiant $U-B$ colors, perhaps several tenths of a magnitude. This is one area that could be vastly improved with more photometry, with the caveats that reddening is often a huge factor for these intrinsically bright, usually distant stars and the fact that fast rotation introduces an inclination angle dependence in the colors. Users wishing to avoid this entirely may want to feed our interpolation program artificially high gravities for stars hotter than about 9000 K. The second area of debate was that the tabulated $H-K$ colors of Tokunaga (2000) for O supergiants were about 0.09 mag redder than for O dwarfs. In this case, we saw no trace of such a trend in our data: a few stars were that red, but they were all dwarfs. We allowed the polynomial fit (which, in that regime, was a function of temperature alone) to determine the final color-color relation. In the

FIG. 6.— The $H - K$, $V - K$ color-color diagram for uncultured stars. Symbols and line styles are as in Figure 2.

middle of the temperature range, a small gravity dependence was indicated, but no dependence on $[\text{Fe}/\text{H}]$ was ever statistically significant.

In the regime of cool giants, there is a strong evolutionary effect such that metal-poor stellar populations do not generate M-type giants. The rich globular cluster 47 Tucanae is on the cusp, containing 4 long-period variable stars at the tip of its giant branch at $[\text{Fe}/\text{H}] \approx -0.8$. The SMC, at present-day $[\text{Fe}/\text{H}] \approx -0.6$, generates some M and Carbon stars, but mostly because of intermediate-age populations that grow very bright (and cool) asymptotic giant branches. Thus, there is a sharp transition from excellent metallicity coverage for K giants to very limited metallicity leverage for M giants, exacerbated by the fact that M giant abundances are hard to measure. In M dwarfs, where stars of all metallicities exist in our list, there is an interesting, strong convergence of color-color sequences as a function of metallicity so that G dwarfs have a very strong $[\text{M}/\text{H}]$ dependence, there is a transition in K dwarfs, and M dwarf colors have no detectable $[\text{M}/\text{H}]$ dependence. In fitting, therefore, the $[\text{M}/\text{H}]$ dependence was gradually removed for cooler and cooler stars, for the giants because cool, metal-poor stars do not exist, and for the dwarfs because the $[\text{M}/\text{H}]$ dependence removes itself empirically.

2.4. Temperatures

Due to our approach of fitting color-color relations internally as a function of gravity and abundance, attachment of temperature scales could, in principle, be done for any color-temperature relation in any part of the parameter space. The first iteration of this process was to layer color-temperature relations on top of each other until the whole parameter range was covered, and to take the median in regions where more than one relation applied. For FGK giants Alonso et al. (1999a) and Alonso et al. (1999b) were used. These works include a specific $[\text{Fe}/\text{H}]$ dependence, and the average of both $V - I$ and $V - K$ relations were used. For appropriate runs of temperatures and gravities, Vandenberg & Clem (2003)

$V - I$ was translated to $V - K$ via our color-color relations. In a similar manner, the synthetic fluxes of Kurucz (1992b) and Bessell et al. (1989, 1991) fluxes were combined and translated to colors as in Worthey (1994). In this case, both $V - R$ and $V - I$ were translated to $V - K$ via the empirical color-color relations and plotted along with the untweaked $V - K - T_{\text{eff}}$ relations. Tokunaga (2000) developed average color-temperature relations for sequences of supergiants, giants, and dwarfs using literature temperature scales. Bessell et al. (1998) gives color-temperature sequences for solar-abundance dwarfs and giants based on different model atmospheres, and we also referred to the empirical cool giant sequences of Ridgway et al. (1980); Dyck et al. (1996). The color-temperature sequences of Johnson (1966) are also included. For the coolest dwarfs, analysis of the data of Basri et al. (2000) yielded a relation as a function of $I - K$ color, specifically $T_{\text{eff}} = -460.25 \times (I - K) + 4323$, valid for $I - K > 2.9$.

M dwarfs with known angular diameters were also included in the mix. Eclipsing binaries YY Geminorum (Torres & Ribas 2002) and CM Draconis (Viti et al. 1997) were supplemented with interferometrically-derived temperatures from Berger et al. (2006) and, in the case of Barnard's star, from Dawson & de Robertis (2004). VK photometry came from either our own catalog or that of Leggett et al. (2001). The temperature estimates of Berriman et al. (1992) for eleven dwarfs are also plotted. These are more indirect temperature estimates from the ratio of the bolometric flux to the flux at an infrared wavelength, the total to infrared flux ratio method (TIRFM). The position of especially the cooler stars was influential in our adopting a somewhat cooler temperature scale around 3000 K than the bulk of the published calibrations.

The fits are good to a limit of $V - K = 10.2$. Since cool dwarfs and giants have different temperature scales, this corresponds to approximately $T_{\text{eff}} = 2700$ K for solar-metallicity giants and $T_{\text{eff}} = 1830$ K for solar-metallicity dwarfs.

2.5. Bolometric Corrections

The last item to be added was the V -band bolometric correction (BC). Since they were that last item in the chain, BCs could be inserted as a function of color or of temperature and for any passband. As for temperature scales, a variety of empirical and theoretical options were intercompared. The Vandenberg & Clem (2003) BCs were adopted for the middle of the temperature range, supplemented by the Vacca et al. (1996) formula for $4.40 < \log T < 4.75$ for the hottest dwarfs and supergiants. At the cool end, for both giants and dwarfs, the Vandenberg & Clem (2003) BCs drift slightly from most calibrations. For giants, we adopted the average, empirical-plus-theoretical K -band BC from Bessell et al. (1998), read from their Figure 20. For cool dwarfs, we adopt the K -band (UKIRT IRCAM3 system) BCs of Leggett et al. (2001). We extended their polynomial slightly to reach our $V - K = 10.2$ cool limit. One subtlety regarding the Leggett et al. (2001) calibration should be mentioned. They give two polynomial fits to the K -band BC, one as a function of $I - K$ and one as a function of $J - K$. We adopt the $I - K$ version, as the $J - K$ version drifts significantly from the $I - K$ ver-

FIG. 7.— Temperature- $V - K$ calibrations for cool, solar abundance giants. Lines are color-coded for the calibrations of Alonso et al. (1999a,b); VandenBerg & Clem (2003); Tokunaga (2000); Johnson (1966); Worthey (1994); Bessell et al. (1998). Our adopted relation is shown as diamonds.

FIG. 8.— Temperature- $V - K$ calibrations for cool, solar abundance dwarfs. Lines are color-coded for the calibrations of VandenBerg & Clem (2003); Tokunaga (2000); Johnson (1966); Worthey (1994); Bessell et al. (1998) and Basri et al. (2000). Red dots with error bars are M dwarfs from Berger et al. (2006) and magenta open circles are TIRFM temperatures and photometry from Berriman et al. (1992). YY Geminorum's temperature is from Torres & Ribas (2002), Barnard's star from Dawson & de Robertis (2004), and CM Draconis's from Viti et al. (1997). Our adopted relation is shown as diamonds.

sion at warmer temperatures. The cause of this drift is increased scatter in the $J - K$ diagram, or, more fundamentally, the fact that both J - and K -bands are on the red tail of the blackbody curve for the warm half of the temperature range covered, so that $J - K$ as a temperature indicator has a small temperature range per unit error.

Note that, plotted as a function of color, and as predicted by synthetic fluxes, the bolometric corrections are

FIG. 9.— V -band bolometric corrections for dwarfs and giants. The top panel is a sequence of giants, and the bottom panel is a sequence of dwarfs, both for near-solar metallicity. The symbol key is marked on the plot itself with sources Vacca et al. (1996) for hot stars, Houdashelt et al. (2000) for cool stars, VandenBerg & Clem (2003); Bessell et al. (1998); Worthey (1994); Plez, Brett, & Nordlund (1992); Brett (1995), and Leggett et al. (2001), plus “PHOENIX,” which refers to fluxes produced from the Phoenix code (Allard & Hauschildt 1995) with colors generated as in Worthey (1994) and “Plez 1997,” which refers to a private communication that was subsequently published in Bessell et al. (1998).

a very weak function of abundance and gravity. This is a degeneracy. That is, increasing a cool giant's abundance (for example) will make it redder and give it a larger (absolute value of the) V -band BC. Such vectors lie closely along the trend caused by temperature, so BCs are strongly covariant with T , $\log g$, and $[M/H]$ when plotted versus $V - K$. We exploit this for cool stars by adopting BCs that vary as a function of color alone. Gravity and abundance dependence then is inherited from the gravity and abundance variations of the color-color diagrams.

3. COMPARISONS AND DISCUSSION

The wealth of comparison data that we could be checking against is too vast to illustrate completely in the pages of this journal, so we limit ourselves to a few key examples. One region of parameter space that is of keen interest is that of low stellar temperatures. We check our results for cool stars against VandenBerg & Clem (2003), Lejeune et al. (1998), an update of the Green (1988) color table used in the Yonsei-Yale isochrones (Yi et al. 2001), and, for good measure, the synthetic colors of Worthey (1994) in Figure 10. The coolest giants are very important for integrated-light studies of spectral features such as TiO that become strong only in these stars, and for surface brightness fluctuation (SBF) magnitudes, especially at red colors, that depend on these stars because of the L^2 dependence of an SBF magnitude.

In Figure 10 our fits are shown as black lines. They were fitted to the $B - V - V - K$ and $V - I - V - K$ diagrams, so it is no surprise that they still fit in this color-color plane. The updated-Green cali-

FIG. 10.— The $B - V$, $V - I_c$ color-color diagram for M stars. Red dots are stars with $[\text{Fe}/\text{H}] > -0.2$ and blue dots are stars with $[\text{Fe}/\text{H}] < -1.2$ with intermediate stars cyan. Giants are open symbols, which dwarfs are filled. The data are uncultured. Calibrations for giant and dwarf color-color sequences are drawn in solid for $[\text{Fe}/\text{H}] = 0$, dashed for $[\text{Fe}/\text{H}] = -1$, and dotted for $[\text{Fe}/\text{H}] = -2$. The color codes for different authors are noted in the figure (“Lejeune” is Lejeune et al. (1998), “Green” is the updated Green (1988) table, and “V&C” is Vandenberg & Clem (2003)).

bration follows an extrapolation of the giant sequence off into regions not occupied by stars, while the dwarf sequence for solar abundance follows the stars very well. There is considerable metallicity dependence in the Green calibration that the stars do not appear to share. The Vandenberg & Clem (2003) sequences follow both dwarfs and giants fairly well, with a fairly good (small) abundance dependence. The oscillations in the solar metallicity giant track are a reflection of actual values in their data tables. The coolest temperature reached by Vandenberg & Clem (2003) is 3000 K. The Lejeune et al. (1998) calibration is based on corrected synthetic fluxes. In this case, the dwarfs and giants track together with little or no gravity separation until, at a temperature well within the tabulated range of applicability, the values become wild.

Besides author comparisons, another way to check our results is to plot colors that were not fitted explicitly to see if the implicit color dependences are correctly modeled. $R - I$ is one such, and is illustrated in Figure 11. For this color, the fits were versus $V - R$ and $V - I$, for slightly different samples of stars. The $R - I$ fitted tracks fall among the stars fairly well, except for a reversal seen around $V - K = 1.5$ where the giants become ≈ 0.02 mag redder than the dwarfs. This 0.02 mag shift is probably incorrect, but it gives a valuable indication of the reliability of the color-color fits.

Reliability must be a function of temperature regime. One particular troublesome area is that of K-type dwarfs and the damping of the abundance sensitivity going toward cool stars. In Figure 12, a T_{eff} of 5000 K corresponds to $V - K \approx 2.2$ and $T_{\text{eff}} = 4000$ K corresponds to $V - K = 3.4$. It is clear that the magic combination of full photometry plus a good abundance estimate is lack-

FIG. 11.— $R - I$ is plotted as a function of $V - K$. Stars of different giant/dwarf status and abundance are plotted with different symbols according to the key. Stars with $[\text{Fe}/\text{H}] > -0.2$ are considered metal rich, stars with $[\text{Fe}/\text{H}] < -1.2$ are considered metal poor, and stars between these values are considered intermediate in metallicity. Lines are coded as in Figure 10. This color was not fit during the calibration process.

ing from our data set for dwarfs. Note the general lack of open symbols (dwarfs) compared to filled (giants). This lack of data means that the metallicity dependence of the dwarfs is inherited from the plentiful giants in this temperature regime; an undesirable feature. At redder colors, as their surface gravities diverge, the dwarfs and giants separate in color. Simultaneously, the metallicity dependence appears to reverse, at least in the giants. It is unclear from the present data what should be happening with the dwarfs. The polynomials do their best to smoothly flow through all of this, but we judge it unlikely that they have truly captured the essence of the color behavior in this regime, as it is not clear to our eyes exactly what should be happening (it seems likely that some of the photometry is bad). This particular problem is an issue only for $U - B$ and $B - V$ colors, although the paucity of K dwarf data is of some concern for all colors, as the metallicity dependence is relatively unconstrained.

The principle source of error in the color-color fits is finding a suitable polynomial to follow the various twists and turns that the colors take. We fit the colors in five segments, with multiply-redundant overlap in color, and used the overlap regions to estimate the error from polynomial fitting. With typically hundreds of stars available for each fit, random photometric uncertainty is not a concern (though, of course, systematic uncertainty is). The median fit uncertainty over all temperatures, gravities, and abundances is listed in Table 1. We also thought it useful to propagate errors in the final subroutine so that uncertainties in the effective temperature scale could be translated to uncertainties in color. For this we used the various T_{eff} relations plotted in Figures 7 and 8 and a couple of others to roughly estimate a percentage error as a function of temperature. This is given in Table 2. Note that the errors in Table 2 for cool stars are more ap-

FIG. 12.— The figure show a small section of the $B - V$, $V - K$ color-color diagram. Dwarfs are drawn with larger symbols than giants for emphasis according to the key in the figure. Stars with $[\text{Fe}/\text{H}] > -0.2$ are considered metal rich, stars with $[\text{Fe}/\text{H}] < -1.2$ are considered metal poor, and stars between these values are considered intermediate in metallicity. Calibrations for giant and dwarf color-color sequences are drawn in solid for $[\text{Fe}/\text{H}] = 0$, dashed for $[\text{Fe}/\text{H}] = -1$, and dotted for $[\text{Fe}/\text{H}] = -2$. At red color, the dwarfs follow the bluer $B - V$ tracks. This is a region of uncertainty, as discussed in the text.

TABLE 1

$V - I$	0.011
$J - K$	0.004
$H - K$	0.002

plicable to giants than dwarfs; dwarf temperatures seem more uncertain than those of giants, but we didn't have enough dwarf calibrations to estimate this very well, so we left it alone. For color I with color error σ_I and a temperature error σ_T , errors propagate in the elementary way:

$$\sigma^2 = \sigma_I^2 + \left(\frac{dT}{dT}\sigma_T\right)^2. \quad (1)$$

Color-color diagrams have been used to derive a “color excess” from which can be inferred a value for the dust extinction (Morgan et al. 1953). The metallicity dependent color-color fits of this paper offer a general, if not overly precise, method of generating a color-color plot for any color combination as a function of abundance and gravity. The classic $U - B$, $B - V$ diagram is shown in figure 13 for dwarfs only. The double inflection redward of zero color represents the rise and fall of the Balmer break in B-type through A- and F-type stars. A defect of this method is that it only works on clusters that have

A-type stars, that is, ones younger than about 1 Gyr that still have dwarfs that hot. Interestingly, there is an additional color inflection in the M dwarfs, roughly between 4000 K and 3000 K, that may allow independent reddening estimates for old clusters that have deep photometry. This inflection exists in almost every color, although the U band presents the most dramatic manifestation of it.

If the U band is utilized, the coolest stars involved have $U - I = 5.65$ mag according to our colors and $M_I = 9.0$ according to diagrams in Leggett (1992). This leads to an absolute $M_U = 14.65$ mag. If a modest telescope can reach $U = 23$ as the KPNO 2.1-meter did in Kaluzny & Rucinski (1995), then the U flux is readily detectable to about 500 pc distance. For reference, the nearest ancient open cluster is M67 at about 800 pc, so one would need a slightly larger telescope or better U sensitivity for U to be useful. However, redder colors can also be made to work at about the same confidence level relative to the fitting errors. The fitting errors are shown as error bars on points in Fig. 13, as is another color sequence shifted by $A_V = 0.1$, shown as a line. We judge that this extinction is the smallest that can be detected at all simply using the color-color fits we present, and so is not particularly competitive with other methods as it stands. Interestingly, at redder passbands, the M-type deflection becomes less pronounced but the errors also decrease so that the $A_V = 0.1$ extinction vector stays at about the same statistical significance in most color-color planes. This does not solve the problem, however, because observational measurement error becomes larger than the fit error at JHK wavelengths. Future refinements to this reddening estimation method are possible and should be encouraged.

4. SUMMARY AND CONCLUSION

Johnson/Cousins photometry was combined with literature $[\text{Fe}/\text{H}]$ estimates to fit color-color diagrams as a function of gravity and abundance. Literature-average temperature and bolometric correction scales are attached to provide a global color-temperature relation for stars with $-1.06 < V - K < 10.2$. The RI magnitudes are in the Cousins system, and JHK magnitudes are in the Bessell homogenized system. The complete color-temperature table and a Fortan interpolation program is available at <http://astro.wsu.edu/models/>.

Several areas of improvement were noted in the main body of the paper, including filling photometry gaps, obtaining more accurate and on-system photometry, know-

FIG. 13.— The final color-color calibration for dwarfs only is shown in the $U-B$, $B-V$ plane as dots with error bars attached, where the error bars include fitting uncertainties and T_{eff} uncertainties. An additional line is shown that represents the color shift due to dust screening of $A_V = 0.1$ mag. For illustrative purposes, a vector for $A_V = 1.0$ mag is also sketched. The approximate blue limits of the bluest dwarfs at the main sequence turnoffs of isochrones of various ages are marked with the corresponding ages. Near the red bump feature, stellar effective temperatures (degrees K) are indicated.

ing better $\log g$ and $[Fe/H]$ values, improving the statistics for data-impovertished groups of stars such as K dwarfs, applying small tweaks in the processing pipeline, and obtaining better empirical temperature and bolometric correction relations, especially for supergiants and M stars.

A way to estimate dust extinction from M dwarf colors arises from an inflection that exists in most colors relative to $V-K$. Unlike the classic UBV method, it can be used in old star clusters, but it does not seem to promise much, if any, increase in accuracy for clusters where both methods apply. The most sensitive band relative to photometric error for the new extinction measure is the U band, but if the U band is employed then clusters must be within a few hundred parsecs for ground-based observatories to be able to measure adequate U fluxes.

Major funding was provided by the National Science Foundation grant AST-0307487, the New Standard Stellar Population Models project. The SIMBAD data base, NASA's Astronomical Data Center, and NASA's Astrophysics Data System were indispensable for this project. GW would like to thank the undergraduates who have typed in data pertaining to stars over the more than 11 years this project has stretched. Brent Fisher (Worthey & Fisher 1996) and Joey Wroten at the University of Michigan and Jared Lohr and Ben Norman at Washington State University.
